25 Abstract

Misidentification between Taylorella equigenitalis, the causative agent of contagious 26 equine metritis (CEM), and Taylorella asinigenitalis is observed by the gold standard culture 27 method. The performance of MALDI-TOF MS for Taylorella species identification was 28 evaluated using 85 T. equigenitalis and 28 T. asinigenitalis strains selected on the basis of 29 multilocus sequence typing (MLST) data. Seven of the T. equigenitalis and nine of the T. 30 asinigenitalis strains were used to generate in-house reference spectra to expand the existing 31 commercial Bruker database. Two bacterial incubation times and three different sample 32 preparation procedures were compared. Overall, we demonstrated the usefulness of MALDI-33 TOF MS as a differential diagnostic tool for CEM; however, commercial spectra databases 34 should be expanded with T. asinigenitalis reference spectra to achieve the expected 35 performance. Moreover, direct spotting of 48 h colonies was not only the most efficient 36 37 protocol, but also the easiest to implement in a clinical setting.

39

40 Keywords: MALDI-TOF MS; *Taylorella equigenitalis*; *Taylorella asinigenitalis*; contagious
41 equine metritis; infectious equine disease.

42

43 **1. Introduction**

The Taylorella genus classified in the Alcaligenaceae family is divided into two 44 species, Taylorella equigenitalis (Sugimoto et al., 1983) and Taylorella asinigenitalis (Jang et 45 al., 2001). T. equigenitalis is reported from the genital tract of horses and rarely of donkeys, 46 and causes contagious equine metritis (CEM), a sexually transmitted disease, included in the 47 World Organisation for Animal Health (OIE) list of notifiable terrestrial and aquatic animal 48 diseases (http://www.oie.int/en/animal-health-in-the-world/oie-listed-diseases-2019/). CEM 49 was first reported in 1977 in the United Kingdom and Ireland from Thoroughbred horses 50 (Crowhurst, 1977; Timoney et al., 1977), and is currently detected worldwide in various horse 51 breeds. The high contagiousness and substantial economic losses associated with CEM led the 52 Horserace Betting Levy Board (HBLB) to develop a Code of Practice for swabbing mares and 53 stallions and for horse breeding disease management (http://codes.hblb.org.uk/) (Allen and 54 55 Wilsher, 2018). T. asinigenitalis is reported from the genital tract of donkeys and less frequently horses, but is not considered to be pathogenic. The gold standard in CEM diagnosis 56 57 is the culture method (OIE, 2012), but misidentification with T. asinigenitalis is observed since phenotypic tests (based on catalase, oxidase and phosphatase activities, and reactivity 58 with T. equigenitalis-specific antiserum) are not sufficiently discriminating. Alternative 59 methods such as indirect immunofluorescence (IIF) (Breuil et al., 2010), polymerase chain 60 reaction (PCR) (Breuil et al., 2011) and 16S rDNA sequencing are still needed. 61

Matrix-assisted laser desorption ionization-time of flight mass spectrometry (MALDI-TOF MS) has emerged as a new technology to replace conventional phenotypic tests for species identification and is increasingly used in many diagnostic laboratories worldwide. Despite (*i*) the high initial cost of the MALDI-TOF equipment and (*ii*) the accessibility to an exhaustive spectral database for the bacterial species identification, MALDI-TOF MS identification is rapid, accurate and less expensive in routine use than molecular and

immunological detection methods (Patel, 2015; Singhal et al., 2015). The results of 68 identification using MALDI TOF MS depend on the microorganism, sample preparation 69 procedure, the matrix used for the reaction, and mostly the spectra present in the database 70 used to obtain the identification. Within this context, we aimed to evaluate the performance of 71 MALDI-TOF MS for the identification of Taylorella species. Two different bacterial 72 incubation times and three different sample preparation procedures were compared. Sixteen 73 in-house *Taylorella* reference spectra were generated during this study to expand the existing 74 75 commercial Bruker database to 10 reference spectra per Taylorella species.

76

77 2. Materials and methods

78 2.1. Bacterial strains, their identification and selection

A total of 113 Taylorella species strains were analysed in this study: 110 isolates and 79 80 three reference strains from the Collection Institut Pasteur (CIP, France): T. equigenitalis CIP 79.7^{T} (= ATCC 35865 = NCTC11184), *T. equigenitalis* CIP 79.44 (= NCTC 11225), and *T.* 81 asinigenitalis CIP 107673^T (= UCD-1 = ATCC 700933). Selection of isolates was based on 82 83 MLST data previously obtained according to the Duquesne et al. (2013) MLST scheme developed for both Taylorella species, and available in the Taylorella MLST database 84 (https://pubmlst.org/taylorella/). Isolates were 83 T. equigenitalis strains from 71 horses and 85 two donkeys (at least 35 males and 22 females) located in France (77%), Belgium, Poland, 86 Switzerland, the United Arab Emirates and unknown geographical locations, and 27 T. 87 asinigenitalis strains from six horses and 11 donkeys (at least 14 males and one female) 88 located in France (82%), Belgium, Sweden and Switzerland. They were identified at the 89 institutions of origin at least using the gold standard culture method according to OIE (OIE, 90 2012) or national culturing instructions for the detection of CEM, e.g. AFNOR standard NF 91 U47-108 (AFNOR, 2012) for strains isolated in France. On receipt of isolates at the Dozulé 92

Laboratory for Equine Diseases (ANSES, France), which is appointed as the French reference
laboratory for CEM and the European Union reference laboratory for equine diseases other
than African horse sickness (<u>https://eurl-equinediseases.anses.fr/</u>), the *Taylorella* species was
confirmed using a *T. equigenitalis*-specific IIF technique (Breuil et al., 2010) and *Taylorella*species-specific PCRs (Duquesne et al., 2007; Breuil et al., 2011). Isolates and reference
strains were maintained using cryobeads at -80 °C.

99

100 *2.2. MALDI-TOF MS*

All isolates and reference strains were subcultured on ready-to-use chocolate agar with 101 polyvitamin supplement (BioMerieux, France) for 48 h and 72 h at $37\pm2^{\circ}$ C in 7% (v/v) CO₂ 102 in air, and identified using a Microflex LT mass spectrometer (Bruker Daltonics, Germany) 103 with MALDI BioTyper and FlexControl V3.0 software. Three different sample preparation 104 105 procedures were tested on three colonies per strain and per sample preparation procedure: (i) direct transfer (spotting) of the colony onto a target plate, (ii) formic acid overlay method that 106 107 consists in depositing 1 µl of formic acid on direct colony spotting, and total protein 108 extraction (only for T. asinigenitalis species) using the acetonitrile/formic acid protocol, according to the Bruker Daltonics manufacturer's recommendations. For the total protein 109 extraction, one colony was suspended in 300 µl of ultrapure water, vortexed and added to 900 110 ul of ethanol. After centrifugation at 16,000 g for 2 min, the supernatant was discarded and 111 the pellet was dried at room temperature without a secondary centrifugation step. The dried 112 pellet was mixed with 10 µl of 70% acid formic solution and then with 10 µl of acetonitrile 113 solution. After centrifugation at 16,000 g for 2 min, 1 µl of supernatant was spotted onto a 114 target plate in three replicates. For each protocol tested, dried deposits were overlaid with 1 µl 115 of 10 mg/ml of α-cyano-4-hydroxycinnamic acid (HCCA) matrix solution (Bruker Daltonics, 116 Germany). The MALDI Biotyper system was calibrated with a Bruker Bacterial Test Standard 117

(*Escherichia coli* DH5α), and the spectra for proteins with mass between 2 000 to 20 000 Da
were obtained and matched with the Bruker V7.0.0 database, composed of 8 223 mass
spectrometry profiles (MSPs), including three *T. equigenitalis* MSPs from strains DSM
10668^T, GDD 39 and GDD 40, and one *T. asinigenitalis* MSP from the CIP 107673^T strain.

The implementation of in-house reference MSPs was done using seven T. 122 equigenitalis strains and nine T. asinigenitalis strains, to expand the Bruker database. MSPs 123 were generated using 26-32 spectra from total protein extracts spotted onto a target plate in 124 eight replicates, and each spot was analysed four times. All raw spectra were done with a laser 125 frequency of 60 Hz, an acceleration voltage of 20 kV and extraction delay time of 120 ns, and 126 analysed according to the established MSP protocol of the Maldi Biotyper[®] V1.1 to remove 127 suboptimal spectra. Preprocessing of the MSP was done using the Biotyper MSP creation 128 standard method (Bruker Daltonics, Germany) with a default parameter set for the baseline 129 130 correction (multipolygon with search window 5 and number of runs 2) and the spectral smoothing (Savitzky-Golay with frame size 25). For each strain, two MSPs were generated, 131 132 respecting a repeatability condition (same culture, same analysis).

The cut-off MALDI TOF Biotyper classification scores for identification were those 133 recommended by the manufacturer: <1.70, no reliable identification; \leq 1.99 and \geq 1.70, high 134 genus-level identification; ≥ 2.00 , high species-level identification. The highest score among 135 the replicates of a strain was considered to define the number of unidentified and correctly 136 identified strains. The performance of MALDI TOF MS was evaluated in terms of its 137 typeability and accuracy; typeability refers to the ability of MALDI TOF MS to assign a 138 species name to a sample with a score \geq 1.70, and accuracy is the ability of MALDI TOF MS 139 to obtain the correct species name for a sample. 140

141

142 2.3. Retrospective analysis of MALDI-TOF MS results from a veterinary diagnostic
143 laboratory

The veterinary diagnostic laboratory LABOCEA22 (Ploufragan, France) implemented 144 MALDI-TOF MS in clinical microbiology diagnosis almost 10 years ago (2009-2010). 145 Between 2011 and 2017, microbiological investigations were performed on 4 920 genital 146 samples, including 2 330 from equine species that were all CEM-negatives by the culture 147 method according to AFNOR Standard NF U47-108 (AFNOR, 2012). Isolated bacterial 148 colonies from these microbiological investigations were identified by MALDI-TOF MS using 149 a Microflex LT mass spectrometer with MALDI BioTyper and FlexControl software (Bruker 150 151 Daltonics, Germany). Colonies were directly spotted and overlaid with 1 µl HCCA matrix solution (Bruker Daltonics, Germany) according to the manufacturer's recommendations. The 152 bacterial test standard (BTS, Bruker) was used for instrument calibration. The cut-off scores 153 for identification were those recommended by the manufacturer. 154

155

156 **3. Results**

In all, 113 Taylorella species isolates and reference strains were selected based on 157 MLST data to evaluate the identification and differentiation of T. equigenitalis (n=85) and T. 158 asinigenitalis (n=28) by MALDI-TOF MS. The MLST results of these 113 strains yielded a 159 total of 46 sequence types (ST) distributed in 31 STs for *T. equigenitalis* (0.36 STs/strain) and 160 15 STs for T. asinigenitalis (0.54 STs/strain). Moreover, all strains were previously identified 161 by the gold standard culture method. Each T. equigenitalis strain was T. equigenitalis-specific 162 IIF positive, T. equigenitalis-specific PCR positive and T. asinigenitalis-specific PCR 163 negative, and conversely, each T. asinigenitalis strain was T. equigenitalis-specific IIF 164 negative, T. equigenitalis-specific PCR negative and T. asinigenitalis-specific PCR positive. 165 Among these strains, seven T. equigenitalis and nine T. asinigenitalis were selected based on 166

167 MLST data to generate 16 in-house *Taylorella* reference spectra to expand the existing 168 commercial Bruker database to 10 reference spectra per *Taylorella* species.

Colony diameter reached 1.0-1.5 mm after an incubation time of 48 h for T. 169 equigenitalis and 72 h for T. asinigenitalis on chocolate agar with polyvitamin supplement at 170 37±2°C in 7% (v/v) CO₂ in air. In order to carry out a MALDI-TOF MS analysis as soon as 171 the Taylorella species colonies were visualised, the 48 h and 72 h incubation times were 172 compared. Three isolated 48 h and 72 h colonies per strain and per sample preparation 173 procedure were processed by direct spotting and formic acid extraction, and three isolated 48 174 h and 72 h colonies per *T. asinigenitalis* strain were also processed by total protein extraction. 175 MALDI-TOF MS identifications are presented in Table 1. The MALDI-TOF MS 176 system accurately differentiated both species, T. equigenitalis and T. asinigenitalis. With the 177 existing Bruker database, the results showed typeability of 100% for T. equigenitalis and 93-178 179 100% for T. asinigenitalis, and achieved accuracy of 100%. Overall, 85 (100%) T. equigenitalis strains were identified in all conditions tested with a species-level identification 180 181 of 98.8-100%. Additionally, 26 (93%) to 28 (100%) T. asinigenitalis strains were identified with a species-level identification of only 26-43% after formic acid extraction, 59-61% with 182

direct spotting, and 75-77% after total protein extraction. With the Bruker database expanded with seven *T. equigenitalis* and nine *T. asinigenitalis* reference spectra (Bruker database, expanded), all results showed 100% typeability and accuracy, and all strains per conditions tested were identified with a species-level identification of 100%.

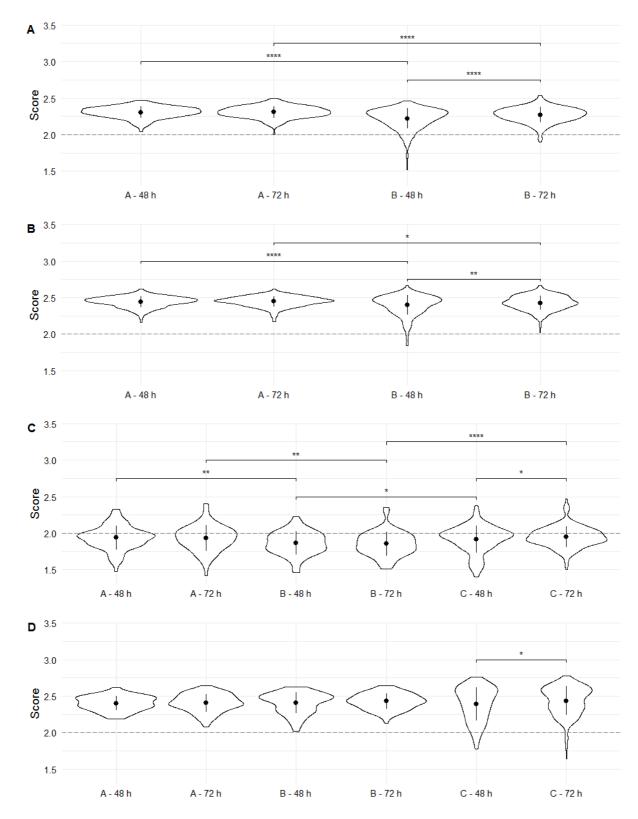

Fig. 1. Violin plots of MALDI-TOF MS scores between Bruker database, expanded or not,
bacterial incubation times, and sample preparation procedures. Spectra from 85 *T*. *equigenitalis* strains (A, B) and spectra from 28 *T. asinigenitalis* strains (C, D) were analysed
against the Bruker database (A, C) or the Bruker database expanded with seven *T*.

201 *equigenitalis* and nine *T. asinigenitalis* in-house reference spectra acquired during this study 202 (**B**, **D**). Three isolated 48 h and 72 h colonies per strain and per sample preparation procedure 203 were processed by direct spotting (A - 48 h and A - 72 h), formic acid extraction (B - 48 h and 204 B - 72 h), and total protein extraction (C - 48 h and C - 72 h); total protein extracts were 205 spotted in three replicates. Dots and error bars represent the mean values and standard 206 deviations, respectively. Statistically significant differences (p < 0.05; two-tailed Student's *t* 207 test) are marked with asterisks (*, p < 0.05; **, p < 0.01; ****, p < 0.0001).

208

MALDI-TOF MS score distributions are depicted using violin plots (Fig. 1). As 209 expected, the score values were increased for *T. equigenitalis* (Fig. 1A and 1B) and especially 210 T. asinigenitalis (Fig. 1C and 1D) with the expanded Bruker database (Fig. 1B and 1D) 211 compared to the Bruker database (Fig. 1A and 1C); the score values for the 85 T. equigenitalis 212 213 strains ranged from 1.52 to 2.54 (mean \pm SD: 2.28 \pm 0.10) with the Bruker database, and 1.84 to 2.67 (2.43 \pm 0.09) with the expanded Bruker database, while the values for the 28 T. 214 215 asinigenitalis strains ranged from 1.33 to 2.47 (1.92 \pm 0.16) with the Bruker database, and 1.64 to 2.78 (2.42 \pm 0.17) with the expanded Bruker database. For *T. equigenitalis*, best 216 results were obtained when colonies were processed by direct spotting compared to formic 217 acid extraction. Significant differences across both bacterial incubation times were observed 218 only when colonies were processed by formic acid extraction, with better results for 72 h 219 colonies compared to 48 h colonies. For T. asinigenitalis, better results with the Bruker 220 database were obtained when colonies were processed by direct spotting and by total protein 221 extraction, compared to formic acid extraction. In contrast, no significant differences were 222 observed across the three sample preparation procedures with the expanded Bruker database. 223 However, interestingly, score distributions with total protein extraction were the most 224 extensive at values <2.00. Concerning the bacterial incubation times, significant differences 225

were observed only when colonies were processed by total protein extraction, with betterresults for 72 h colonies compared to 48 h colonies.

A retrospective analysis of MALDI-TOF MS results from a veterinary diagnostic laboratory (LABOCEA22) on isolated bacterial colonies of 2 330 equine samples, which were all CEM-negatives by the culture method, showed 100% specificity: no *T. equigenitalis* and *T. asinigenitalis* identifications were observed by MALDI-TOF MS.

232

233 **4. Discussion**

In this study, the usefulness and accuracy of MALDI-TOF MS for the identification 234 and differentiation of *T. equigenitalis*, the causative agent of CEM, and *T. asinigenitalis* were 235 evaluated. With the existing commercial Bruker database, including three T. equigenitalis 236 reference spectra and a single T. asinigenitalis reference spectrum, our findings revealed 237 238 excellent MALDI-TOF MS performance at the species-level for T. equigenitalis and at the genus-level for *T. asinigenitalis*. The poorer results obtained with the *T. asinigenitalis* strains 239 240 can be attributed to the presence of a single T. asinigenitalis reference spectrum included in the Bruker database that is not sufficiently representative of the species in circulation, 241 especially in a context where the genetic diversity of *T. asinigenitalis* appears to be higher 242 than that of *T. equigenitalis* (Duquesne et al., 2013). Nevertheless, it is important to note that 243 no T. asinigenitalis were falsely interpreted even though T. equigenitalis is its closest 244 phylogenetic relative, confirming the potential of MALDI TOF MS to perform correct 245 discrimination between both *Taylorella* species. Retrospective analysis of MALDI-TOF MS 246 results from a veterinary diagnostic laboratory, LABOCEA22, confirmed that no T. 247 equigenitalis and T. asinigenitalis were falsely interpreted from all microbiological 248 investigations on CEM-negative equine samples between 2011 and 2017. 249

Finally, the performance of MALDI-TOF MS for the identification of *T. asinigenitalis* 250 251 became excellent at the species-level when the Bruker database was expanded with in-house T. asinigenitalis reference spectra generated during this study. Importantly, the addition of the 252 253 T. equigenitalis reference spectra simply made it possible to improve the score values that were already at species-level identification. Improvement of identification with an expanded 254 database has been shown in various studies on different microorganisms (Christensen et al., 255 2012, Sogawa et al., 2012, Pérez-Sancho et al., 2018). The presence of exhaustive reference 256 257 MSPs in a commercial database is a critical point for this technology for microorganism identification. To meet this requirement, numerous species are needed, along with expansive 258 259 and time-consuming work to obtain a validated database.

Two to three sample preparation procedures were compared during this study. Overall, 260 the easier sample preparation procedure by direct colony spotting seems sufficient to obtain 261 262 excellent MALDI-TOF MS performance at the species-level. In all cases, T. equigenitalis score distributions were significantly increased by direct colony spotting. The differences 263 264 between the sample preparation procedures were less marked for T. asinigenitalis. In fact, no impact of the sample preparation procedure was observed between (i) direct spotting and total 265 protein extraction with the existing Bruker database, and (ii) direct spotting, formic acid 266 extraction and total protein extraction with the Bruker database expanded with in-house 267 Taylorella reference spectra. Nevertheless, T. asinigenitalis score distributions with total 268 protein extraction were the most extensive at values <2.00, while the number of strains 269 identified at the species level was the highest. 270

Two bacterial incubation times were compared during this study. Overall, the shortest bacterial incubation time (48 h compared to 72 h) was sufficient to obtain excellent MALDI-TOF MS performance at the species level. Essentially, differences between the bacterial incubation times tested were either not significant, e.g. with direct spotting for both *Taylorella* species and with formic acid extraction for *T. asinigenitalis*, or they were without any real
impact on *Taylorella* species identification, e.g. with formic acid extraction for *T. equigenitalis* and with total protein extraction for *T. asinigenitalis*.

In summary, we have demonstrated that MALDI-TOF MS is currently a highly 278 reliable tool for the species-level identification of T. equigenitalis and T. asinigenitalis. 279 MALDI-TOF MS could be a useful and rapid differential diagnostic tool to establish the 280 prevalence and epidemiological role of both Taylorella species in the clinical setting. 281 However, existing commercial MALDI-TOF MS spectra databases should be expanded with 282 T. asinigenitalis reference spectra to achieve the expected performance of T. asinigenitalis 283 identification at a species-level. Additionally, for T. asinigenitalis, which has slower growth 284 than T. equigenitalis, direct spotting of 48 h colonies presented overall the most reliable and 285 consistent identification rates, and it was the easiest protocol to implement in the clinical 286 287 setting. On the basis of our findings, we propose to amend the OIE Terrestrial Manual (OIE, 2012) with the addition of MALDI-TOF MS as a differential diagnostic tool for CEM. 288
